APPENDIX I U-238 (Th-234) Measurements in Soil	22
APPENDIX II SUBSURFACE INVESTIGATION LOGS	32

## 1.0 INTRODUCTION

The uranium content of surface soil surrounding the NL Bearings plant in Albany has been reported by Jeter and Eagleson (1980). That study measured soil samples from a radial grid centered at the plant. Two successive soil plug samples were analyzed at each location, one at 0-0.5 inch depth and another at 0.5-2.0 inch depth.

This report documents a survey of uranium on the plant grounds to a depth of 28 feet. It is intended to find whether uranium materials are buried on the site and to measure their geographical patterns and activity levels. A rectangular sampling grid was chosen for this study, having sites more closely spaced in areas where subsurface activity was suspected. Samples were collected by a standard boring method and were analyzed at the Teledyne Isotopes laboratory.

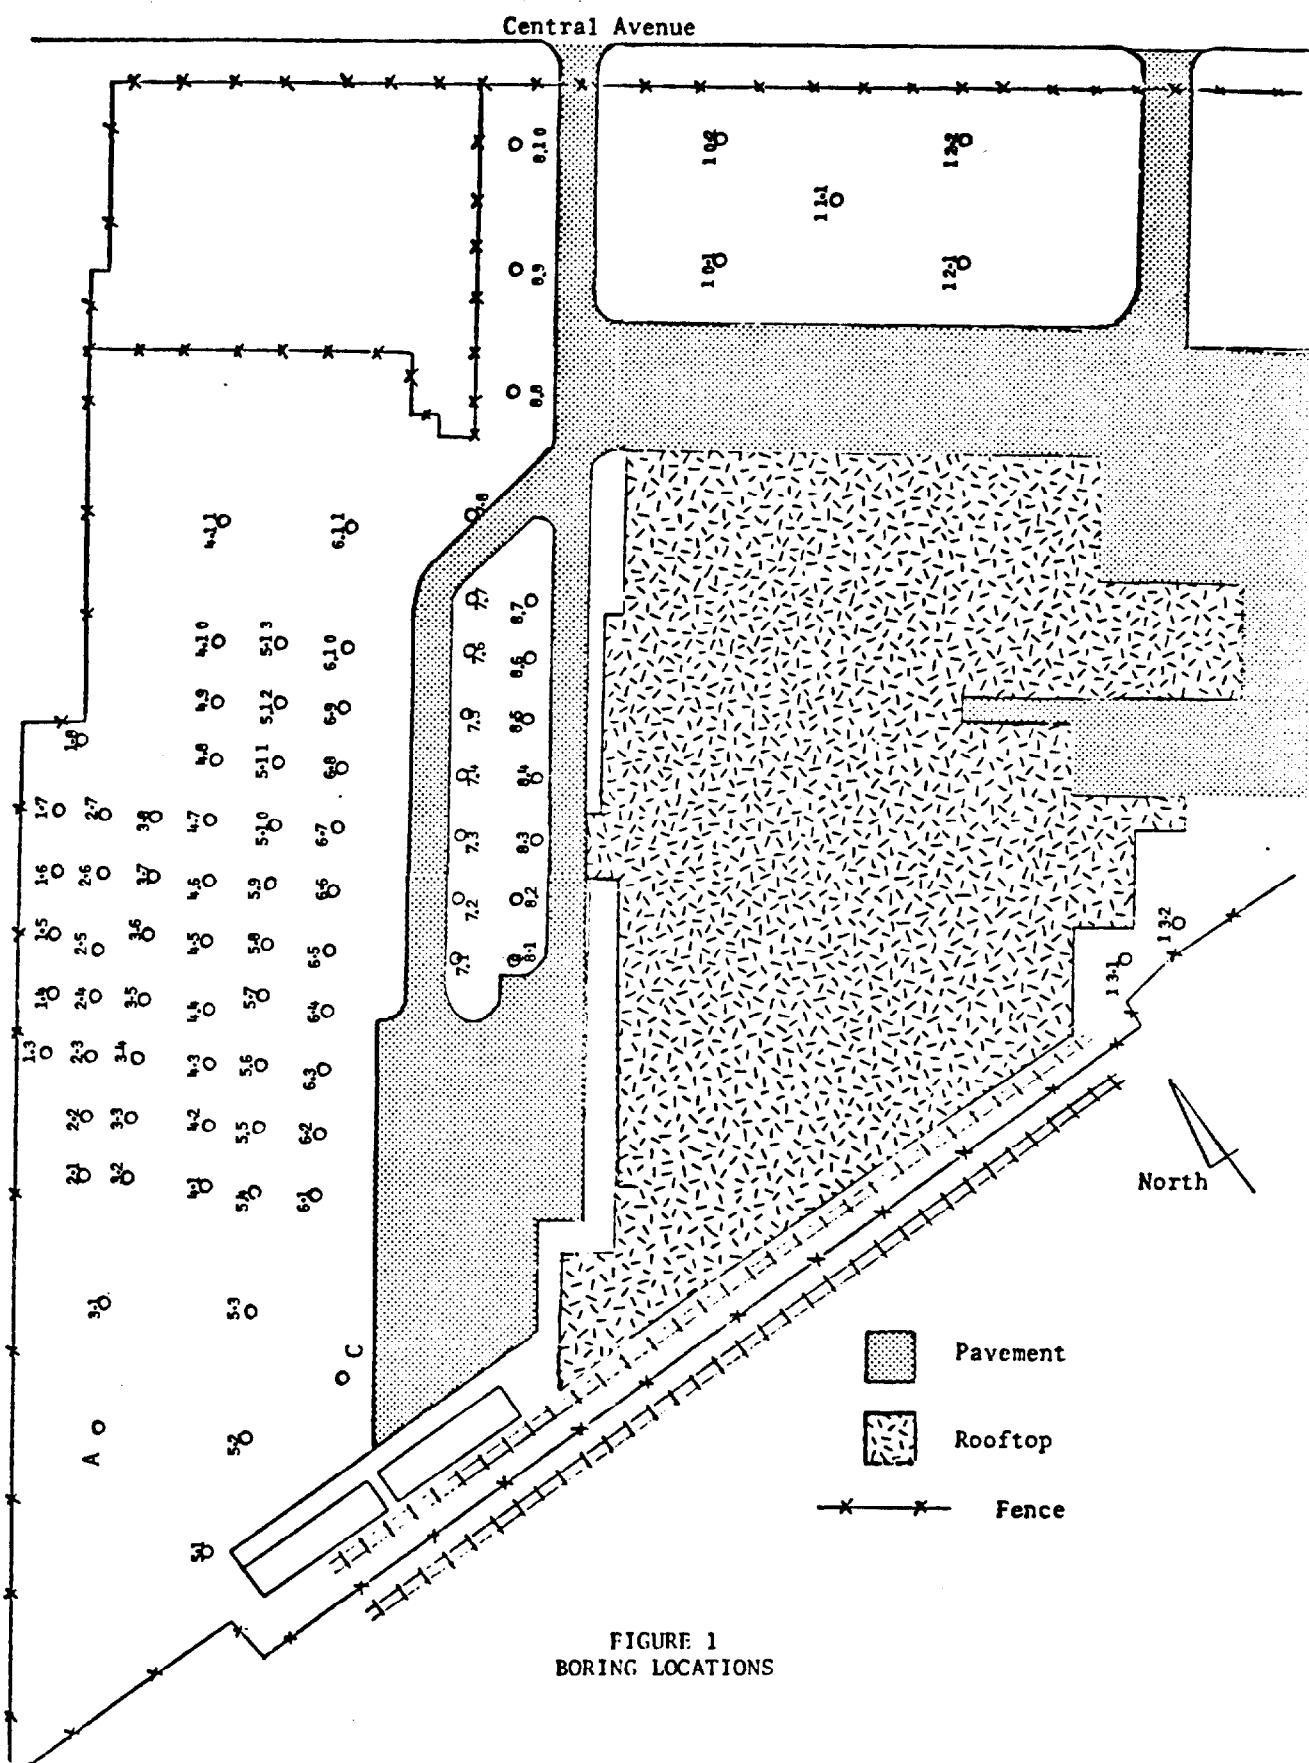

## 2.0 METHODS

There are two general ways in which subsurface radioactivity survey could be conducted. Holes could be bored at the desired locations and an in situ (down-hole) device could be lowered to measure a continuous radioactivity profile. This method has the disadvantage that field measurement systems lack the resolution and reliability of laboratory measurement systems. The alternative is to collect soil samples with a boring device and then subject them to laboratory analysis. This method, which was chosen for the present study, has the additional advantage that samples can be stored for further analyses if the initial results warrant it.

### 2.1 Soil Sampling

Boring locations are indicated by open circles on Figure 1. They are spaced in an approximately square pattern measuring 10 meters on a side in the area of suspected subsurface activity. A spacing of 20 meters is shown in other parts of the plant grounds. The sites are somewhat irregular because of interferences such as power lines. Figure 1 shows the actual locations of the completed holes based on tape measurements from reference points such as the building and fences.

Numbering of boring sites is generally indicated by a row number followed by a decimal point and then a column number. Rows are numbered sequentially eastward beginning at the west fence (1 through 13). Column numbers increase northward but have irregular beginning locations because of obstacles. In row 1 the first column number is 3 because the first two proposed sites were blocked by obstacles. Rows 10 and 12 north of the plant have two boring locations each, and row 11 has only one site. Row 13 has two sites south of the plant. There is no row numbered 9.

Two boring locations west of the plant are designated "A" and "C". These sites were added after the numbering system was constructed and require special identification.

Soil sampling was performed by Empire Soils Investigations, Inc. of Latham, New York. An associate scientist of Teledyne Isotopes was on site continuously to provide quality control. The operation was conducted in March and April, 1981. Three conventional, truck-mounted rotary drill rigs were in operation during most of the project. Each rig had an operating crew of two persons.

Samples were obtained by the standard test boring method ASTM D-1586. This involves driving a "split-spoon" sampling tube into the soil by the fall of a 140 pound hammer tended from the rig. The sampling tube is two feet long with an inside diameter of 1 3/8 inch. After each two foot advance of the sampling tube it is withdrawn and opened along its axis to remove the sample. The advance of the sampling tube is followed by a drive pipe (casing) to retain the hole intact and to prevent the walls from collapsing. All borings were completed to a depth of 30 feet.

Each two foot soil sample was placed in a quart glass bottle provided with a screw top. No attempt was made to keep the core vertically intact during this process. The sampling was continuous in that each successive two foot sample was bottled, leaving no part of the soil column unsampled. Each 30 foot boring resulted in 15 samples although several were lost through spillage..

The drilling crew completed a subsurface log at each boring site (Appendix II). These show observations of soil type, ground water levels, and the number of hammer blows required to advance the sampling tube.

A key to the interpretation of these logs is included at the beginning of Appendix II. The indicated hole numbers begin with "B" (boring), followed by the row and column numbers explained previously. Samples from each hole are numbered sequentially from the surface (1-15).

## 2.2 Sample Preparation

This study is intended to show the depth-dependence of U-238 activity as well as to map its horizontal extent. Because samples were collected over two foot depth increments, it would be possible to analyze 15 levels per boring. This degree of spatial resolution was judged to be unnecessary for an exploratory survey of this sort. It was decided to composite (mix) adjacent samples two-by-two, providing one analysis for a four foot depth increment. An exception was made for the shallowest two samples because fallout contamination of the plant grounds had been established from the previous study. Samples 1 and 2 (0-2 feet and 2-4 feet) were analyzed separately in order to avoid interpreting surface activity as buried activity by mixing to a four foot depth.

All samples were dried before compositing and analysis. This was performed to reduce all results to a consistent dry weight basis. A large fraction of soil samples were taken below the water table such that standing water was observed in the glass containers. Drying was accomplished by removing the screw top and placing the sample bottles in a hot air oven at  $105^{\circ}\text{C}$  for about 48 hours.

Dried samples were removed from their glass containers and then pulverized with a hammer in a galvanized steel pan. This process was continued until no soil particles greater than  $\frac{1}{4}$  inch remained. Large rocks and chunks of wood were removed. The pulverized soil was then mixed by stirring.

The pulverizing and stirring operations described above serve to homogenize the soil sample over the depth interval of collection (two feet for samples 1 and 2 from each boring; four feet for all other samples). This process would dilute any radioactivity localized within the core. For example, a thin layer of fallout at the surface of the uppermost sample would be mixed over the two foot depth interval, thereby reducing its activity on a bulk basis (pCi/gram). Similarly, a thin buried layer would be reduced in concentration by the mixing process. The possible distortion of results mentioned above is preferable to the alternative, which is the risk of missing some activity altogether. If the sample were not mixed and a small portion were taken at random for analysis, a thin layer of activity could remain undetected. In this study, a large fraction of the mixed sample is analyzed in order to avoid the problem.

### 2.3 Analysis of Samples

The U-238 content of soil was determined by gamma spectral analysis of the daughter product Th-234 ( $T_{1/2} = 24$  days), assuming secular equilibrium. Thorium-234 emits gamma rays at energies of 63 and 93 keV. The 93 keV peak, having a branching intensity of 4.7%, was chosen for analysis in this study.

The measurement system employs a Teledyne Isotopes sodium iodide NaI (Tl) detector 5 inches in diameter by 0.5 inch thick. The crystal is surrounded by a 3/16 inch thick cylinder of stainless steel to provide shielding against low energy radiation from the sides. The detector face is recessed 1 cm from the cylinder rim. In operation, the sample and detector were placed in a cage made of  $\frac{1}{4}$  inch thick steel to provide further shielding of low-energy ambient radiation.

The sodium iodide detector was coupled to a Canberra Series 30

multichannel analyzer. Gain was adjusted to 0.25 keV per channel, allowing a viewing range of 5 to 250 keV for the 1024 channels. Spectral information was written on a data form as 3 regions: the peak region (93 keV) having a constant width of 101 channels and two adjacent shoulder regions including approximately 20 channels each. Data reduction was performed on a programmed calculator. Integrated counts in the two shoulder regions were expressed on a per-channel basis and averaged to give the background in the peak region. Subtracting this background from the integrated counts in the peak yields a net count rate for purposes of calculating activity.

Soil samples were analyzed in either of two counting geometries. Both were plexiglass cylinders open on one end, having an inside diameter of five inches (the same as the detector diameter). One cylinder is one inch deep, holding approximately 500 grams of dry soil; the other is  $\frac{1}{2}$  inch deep. The shallower geometry was only used in a few cases where the sample quantity was limited.

To make a measurement, the plastic cylinder was filled to the rim with mixed soil sample and then weighed. The container was placed in the cave and the detector was positioned on top (rim-to-rim). The cave was closed and data acquisition was begun. A counting interval of 500 seconds was used for the one inch geometry and 1000 seconds for the  $\frac{1}{2}$  inch geometry, resulting in a detection limit near 10 pCi/gm.

Calibration of the system was performed by counting a uranium oxide standard mixed with soil in both geometries. The standard soil, containing 649 pCi/gm U-238, was prepared as described in the previous study (Jeter and Eagleson, 1980). The calibration resulted in a counting efficiency of 0.131 for the one inch geometry and 0.170 for the  $\frac{1}{2}$  inch geometry.

Quality control of the measurement system was established by reading a check source and a blank twice per day. The check source consists of one gram of uranium oxide standard spread uniformly over a five inch diameter circle in a flat pan. A thin layer of epoxy covers the uranium in order to keep it in place. The purpose of the check source is not to establish counting efficiency (described above), but to determine whether the measurement system has drifted. The system is judged to be "in control" if the check source reading lies within the two sigma statistical range of its value when calibration was performed. If the measurement system fails this test, it must be adjusted until the test is passed. Similarly, blank readings must result in a detection limit calculation (4.66 sigma level) in order to be acceptable. In other words, analysis of a blank must result in no detectable activity.

### 3.0 RESULTS

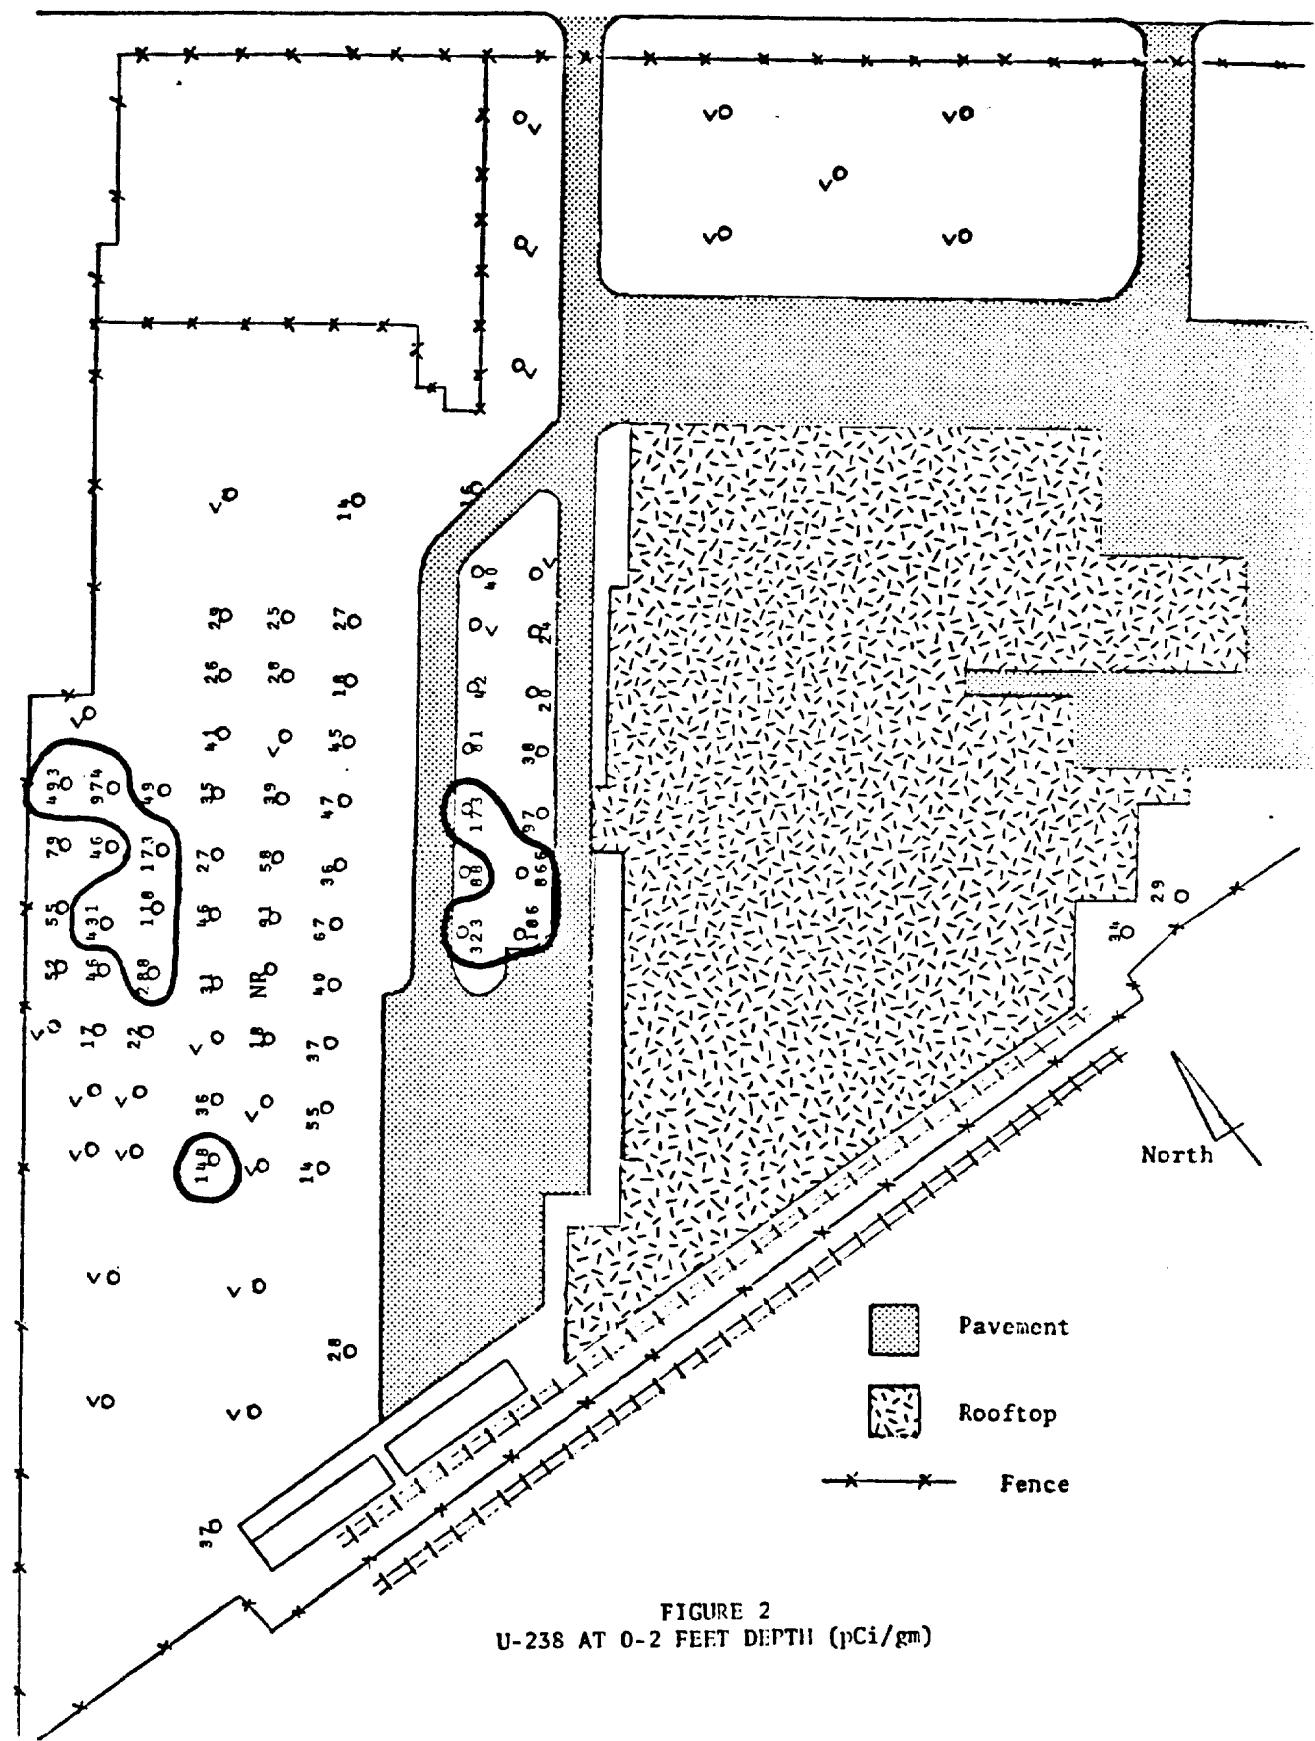

Measurements of U-238 are listed in Appendix I according to boring number and depth increment. Symbols and abbreviations are explained on the appendix flyleaf. Blank spaces in the data tables indicate analyses which were purposely omitted. In these cases, the lack of uranium in the upper part of the soil column indicates that only spot checks are necessary at deeper levels.

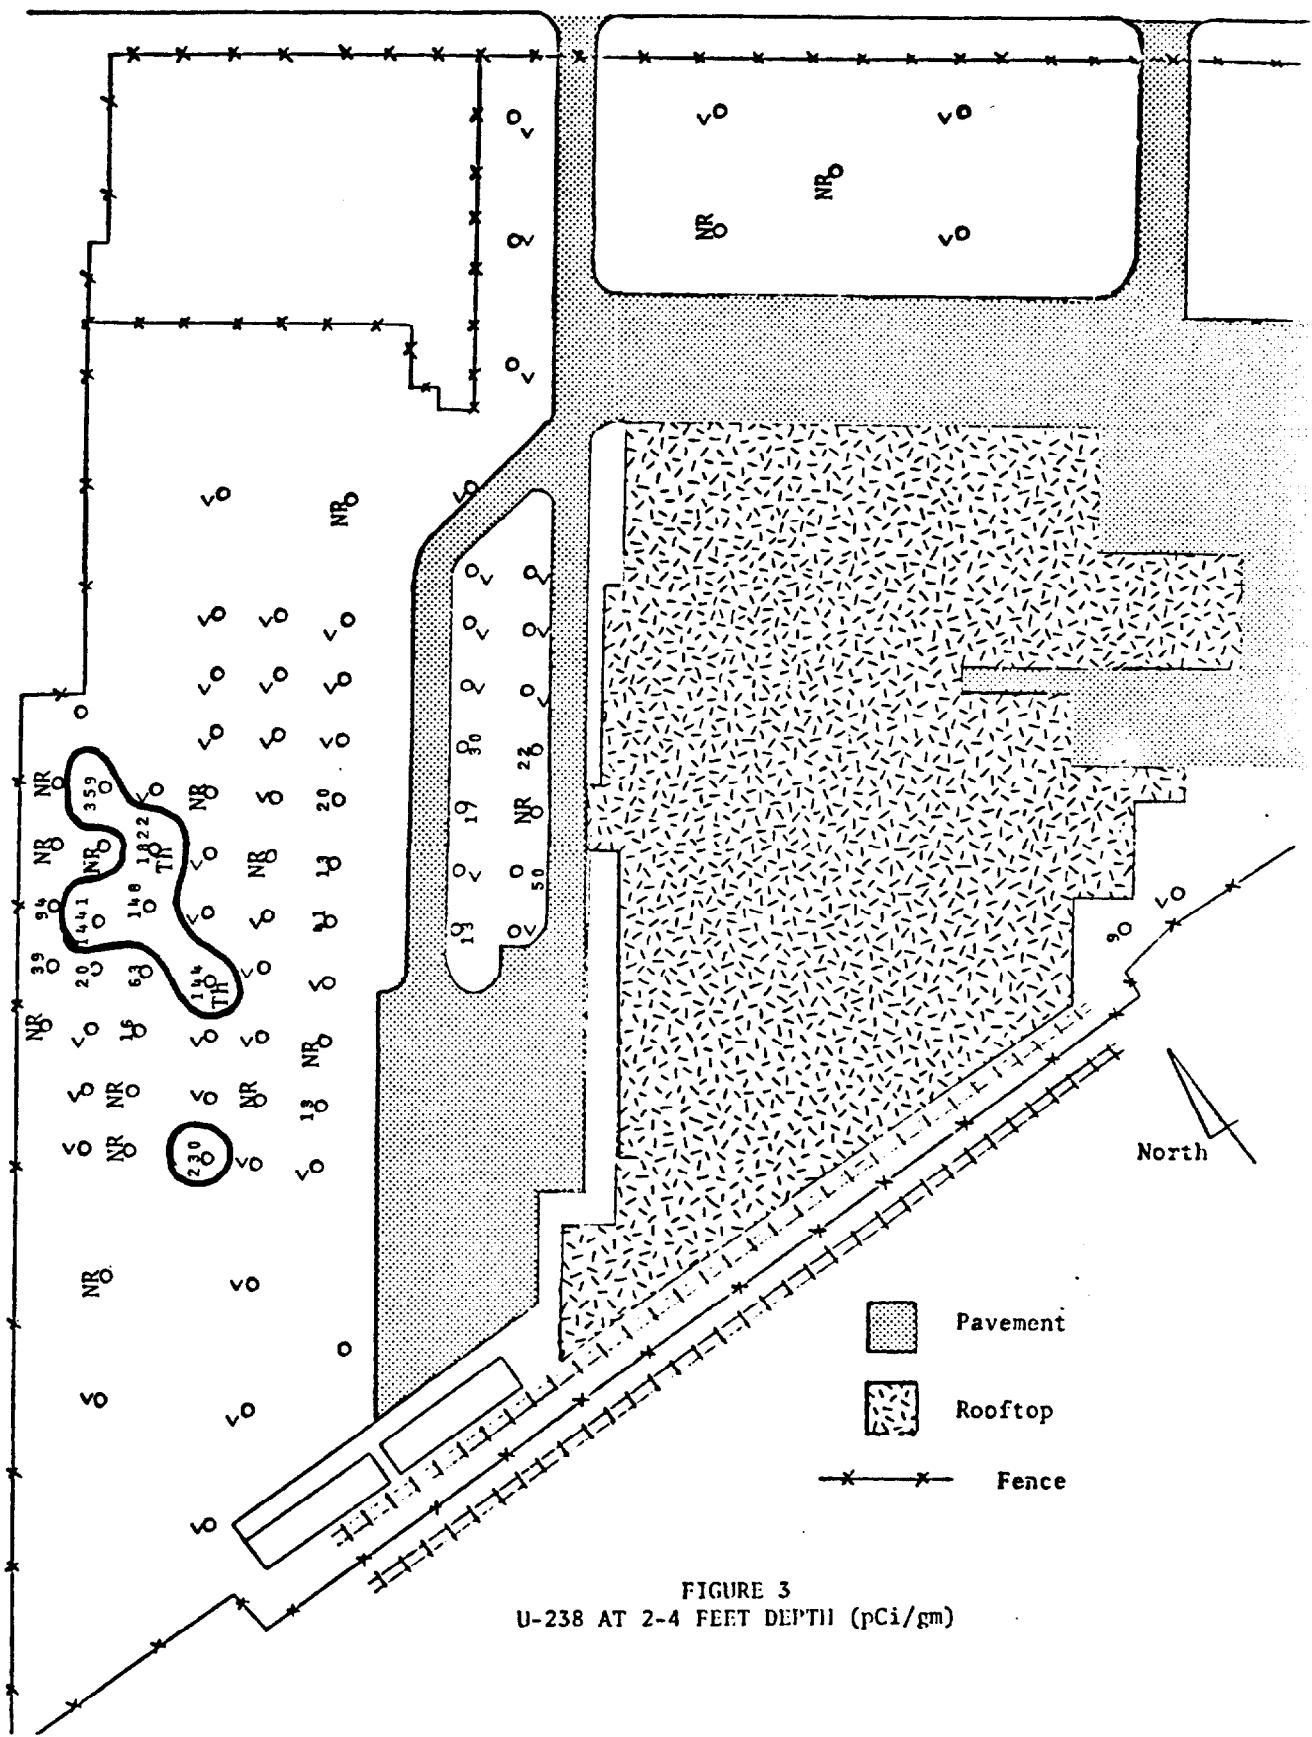

Figures 2 through 9 display the data in plan view at successive depth increments. U-238 activities (pCi/gm dry) are shown near each boring location. A red contour encloses values greater than 100 pCi/gm in order to make patterns of concentration more evident. As in Appendix I, the abbreviation "NR" signifies "no recovery" and the symbol "<" designates a value below detection limits. Boring locations showing no figures or symbols indicate that the sample at that level was not analyzed.

The contours in Figures 2 through 9 indicate concentrations of subsurface uranium west of the plant. The broadest areas of buried radioactivity lie above the 12-foot level: the 100 pCi/gm contours enclose 4 or more boring locations. At depths greater than 12 feet the contours enclose only one or two boring locations at each level. Concentrations exceeding 100 pCi/gm extend to 24 feet at location 1.6 (Figure 8).

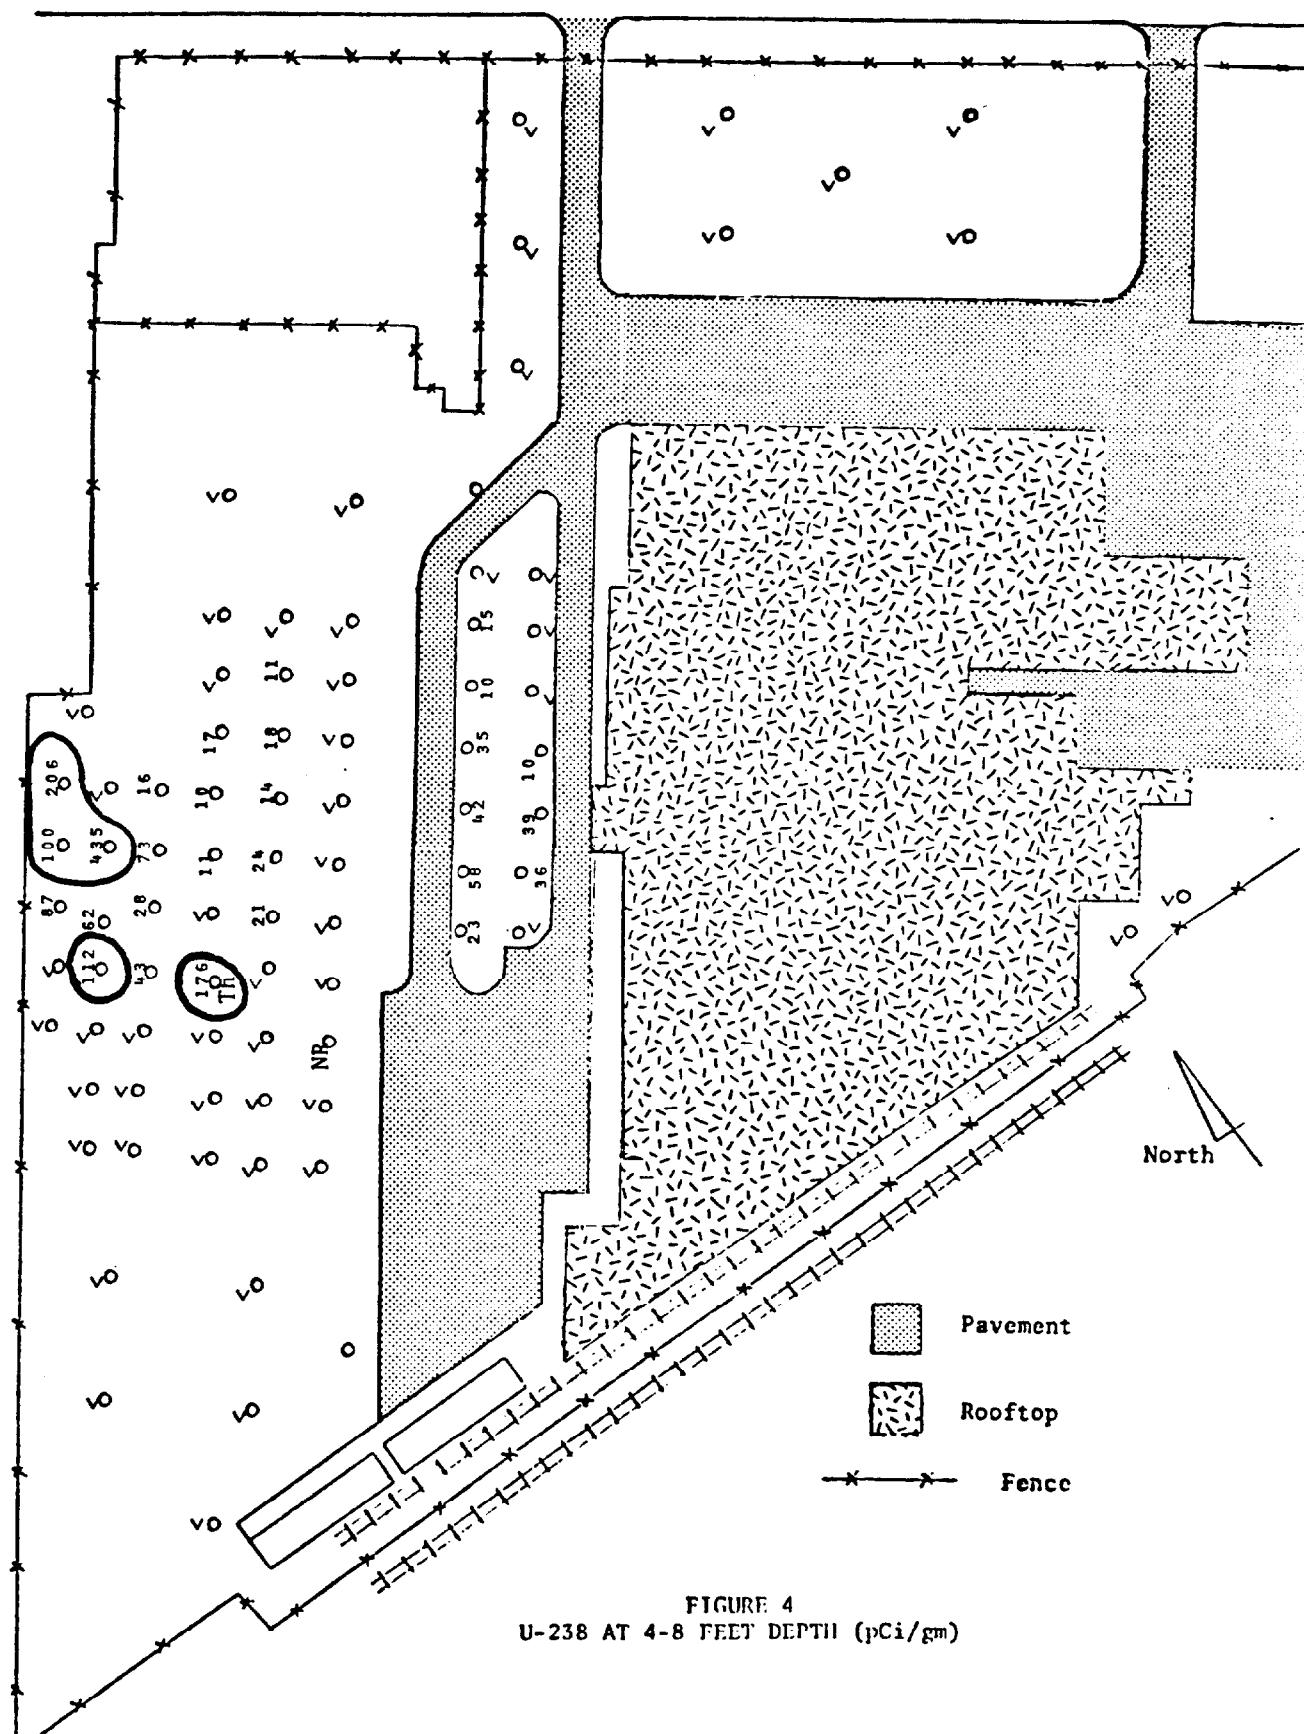

Locations 3.8 and 4.4 on Figure 3, and location 4.4 on Figure 4, are additionally marked with "Th". Samples from these areas exhibited an unusual gamma spectrum and were consequently subjected to high resolution Ge(Li) analysis. This revealed concentrations of Ac-228 as well as U-238 (see Appendix I footnotes). The Ac-228 nuclide ( $T_{1/2} = 6$  hours) is a daughter product of Ra-228 ( $T_{1/2} = 6.7$  years), which is in turn the daughter product of

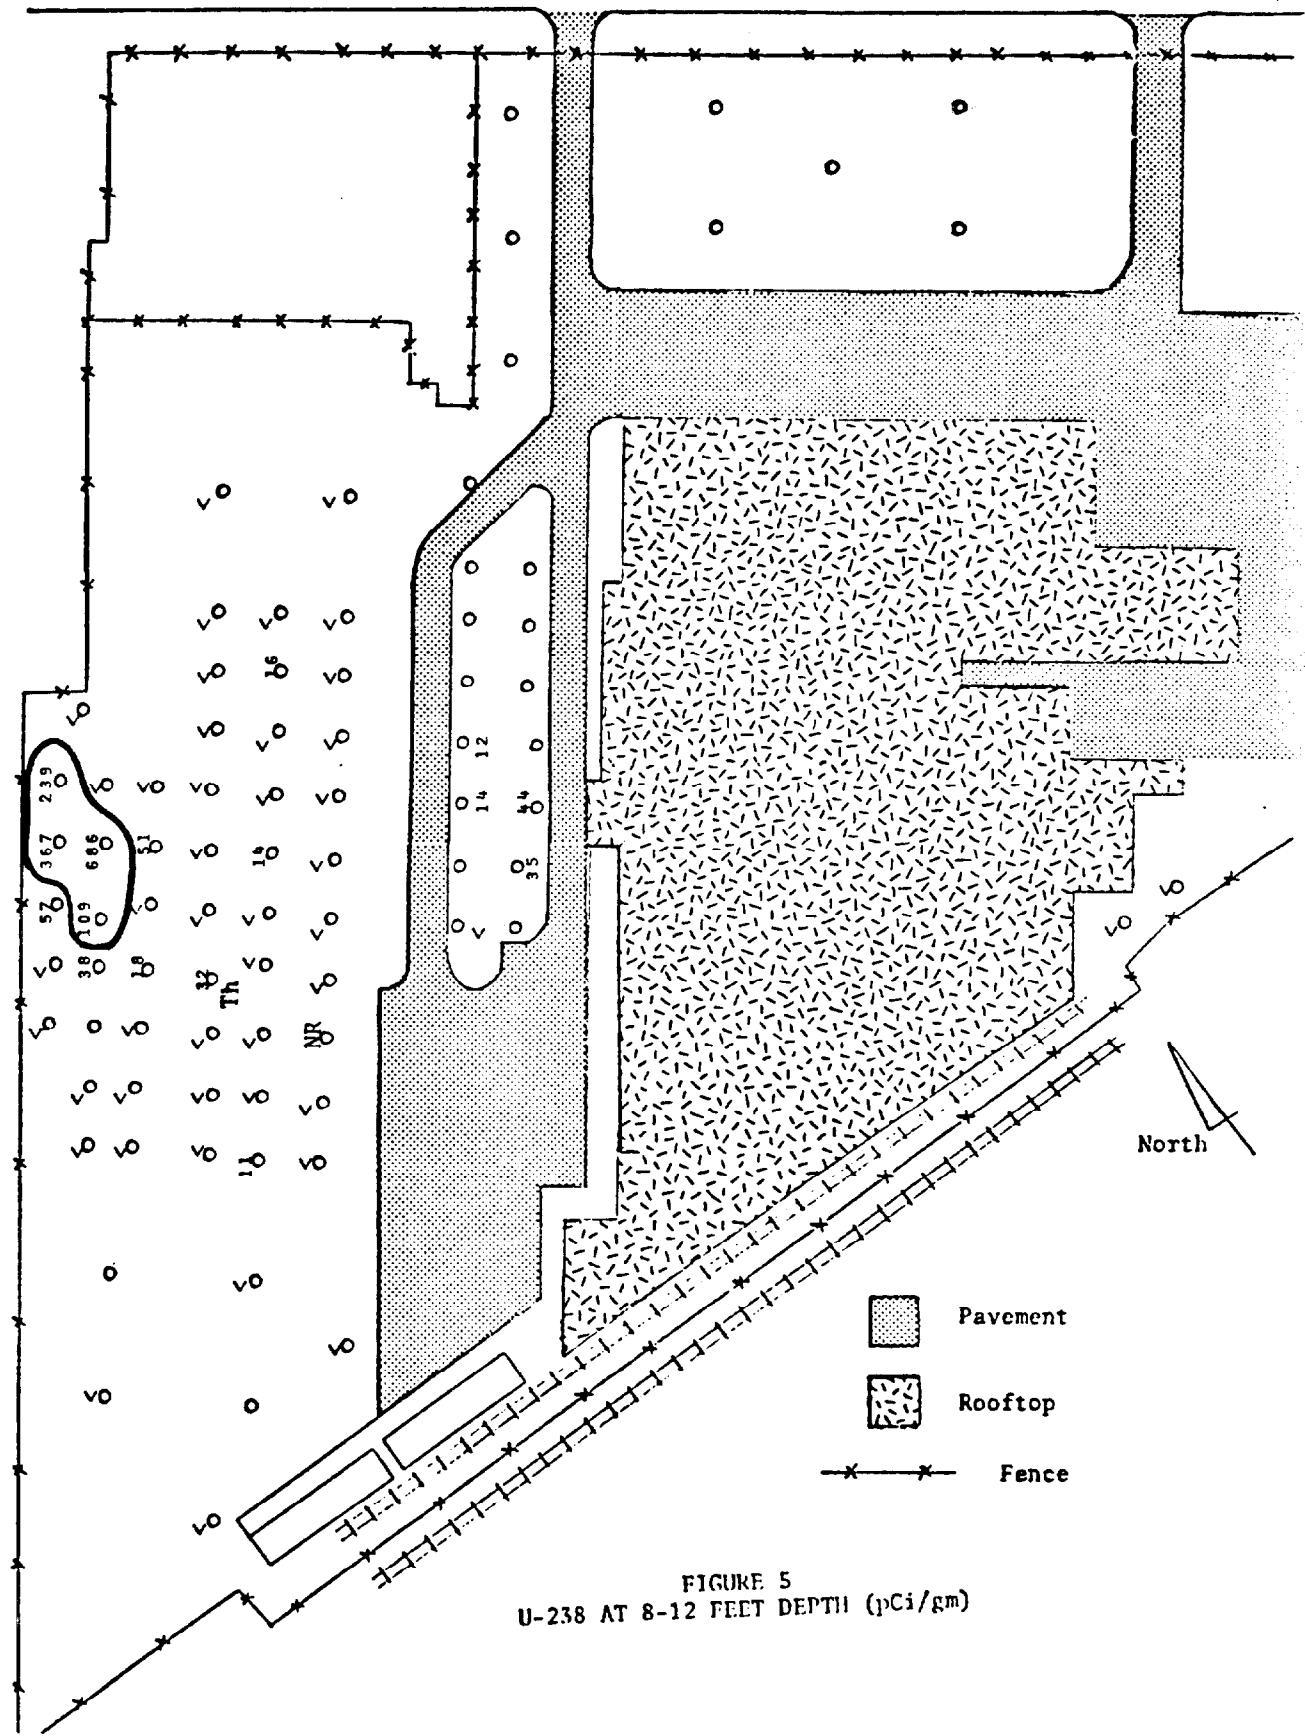

long-lived natural thorium-232. Consequently, the Ac-228 found at these locations indicates the presence of Ra-228 and probably an equivalent activity of buried Th-232 (assuming secular equilibrium).

#### 4.0 SUMMARY

The purpose of this study is to determine the concentration and geographical extent of subsurface U-238 on the grounds of the NL Bearings plant in Albany. Eighty-one test borings were performed to a depth of 30 feet according to standard ASTM procedure D-1586. The boring locations were chosen on a rectangular grid measuring 10 m (33 feet) on a side in the area where underground activity was suspected. A 20 m grid was employed in other parts of the plant grounds.

Soil samples were taken from the test borings at two foot increments. These were packaged in glass bottles and shipped to Teledyne Isotopes. The samples were dried, pulverized, and analyzed for U-238 by spectral analysis of the 93 keV emission of its daughter product Th-234. Samples taken below the four foot level were composited (mixed) two-by-two, such that the analysis represents a 4-foot depth increment. If little uranium was found in the upper half of a boring, alternate samples at deeper levels were omitted to provide a spot check.

Results are presented in tables and in plan-view diagrams for each successive sampling level. At 0-2 feet depth, 11 borings show U-238 activity greater than 100 pCi/gram. At 2-4 feet, 6 borings exceed this activity. Five borings at 4-8 feet, 4 at 8-12 feet, and 2 at 12-16 feet meet this criterion. Below 16 feet, 1 boring at each level exceeds 100 pCi/gm to a depth of 24 feet.

It is important to consider the method of analysis when interpreting results. Soil samples above the 4-foot level were mixed over a 2-foot depth increment. Deeper samples were mixed over a 4-foot increment. This method has the advantage that any thin layers of activity are included because the sampling is continuous. It has the disadvantage that a thin layer of

activity would be diluted by mixing with surrounding soil, making its measured activity (pCi/gm) lower than the true activity in the concentrated layer.

APPENDIX I

U-238 (Th-234) MEASUREMENTS IN SOIL

Activities are expressed in pCi/gm dry.  
Tolerances refer to 2 sigma counting statistics.  
Values preceded by the symbol "<" signify the  
4.66 sigma detection limit when no activity  
is detected. The abbreviation "NR" means "no  
recovery" or insufficient sample for analysis.  
Blank spaces indicate analyses which were pur-  
posely omitted.

**APPENDIX II**

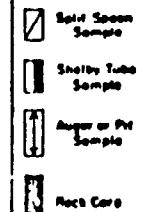

**SUBSURFACE INVESTIGATION LOGS**

Each boring location is presented on a separate page. Classification of soils and observations of groundwater levels were performed by the driller. An explanation of entries is shown first.

## GENERAL INFORMATION & KEY TO SUBSURFACE LOGS

The Subsurface Logs attached to this report present the observations and mechanical data collected by the driller while at the site, supplemented by classification of the materials removed from the borings as determined through visual identification by technicians in the laboratory. It is cautioned that the materials removed from the borings represent only a fraction of the total volume of the deposits at the site and may not necessarily be representative of the subsurface conditions between adjacent borings or between the sampled intervals. The data presented on the Subsurface Log together with the recovered samples will provide a basis for evaluating the character of the subsurface conditions relative to the proposed construction. The evaluation must consider all the recorded details and their significance relative to each other. Often analyses of standard boring data indicate the need for additional testing and sampling procedures to more accurately evaluate the subsurface conditions. Any evaluations of the contents of this report and the recovered samples must be performed by Professionals having experience in Soil Mechanics and Foundation Engineering. The information presented in the following defines some of the procedures and terms used on the Subsurface Logs to describe the conditions encountered.

- ① The figures in the Depth column defines the scale of the Subsurface Log.
- ② The Sample column shows, graphically, the exact depth range from which a sample was recovered. See Table I for a description of the symbols used to signify the various types of samples.
- ③ The Sample No is used for identification on sample containers and/or Laboratory Test Reports.
- ④ Blows on Sampler - shows the results of the "Penetration Test", recording the number of blows required to drive a soil spoon sampler into the soil beneath the casing. The number of blows required for each six inches penetration is recorded. The total number of blows required for the last 12 inches of penetration are summarized in the "N" column. The outside diameter of the sampler, the hammer weight and the length of drop are noted at the bottom of the Subsurface Log.
- ⑤ Blows on Casing - shows the number of blows required to advance the casing a distance of 12 inches. The casing size, the hammer weight and the length of drop are noted at the bottom of the Subsurface Log. If the casing is advanced by means other than driving, the method of advancement will be indicated in the Notes column or under Method of Investigation at the bottom of the Subsurface Log.
- ⑥ All recovered soil samples are reviewed in the laboratory by technicians. The visual descriptions are made on basis of the sample as recovered and in accordance with the Unified Classification System Guide Lines for the terms used in descriptions are presented in Tables II and III. The description of the relative soil compactness or consistency is based upon the penetration records as defined in Table IV. The description of the soil moisture is based upon the condition of the sample as recovered. The moisture condition is described as dry, damp, moist or wet. Water used to advance the boring may have affected the in-situ moisture content of the sample. Special terms are used as needed to describe materials in greater detail, several such terms are listed in Table V. When sampling a gravelly soil with a standard two-inch diameter split spoon, the true percentage of gravel is often not recovered due to the relatively small sampler diameter. The presence of boulders and large gravel is sometimes, but not necessarily, detected by an evaluation of the casing and sampler blows or through the action of the drill rig as reported by the driller.
- ⑦ The description of rock shown is based upon the recovered rock core. Terms frequently used in the description are included in Table VI.
- ⑧ Miscellaneous observations and procedures ruled by the driller are shown in this column, including water level observations. It is important to realize that the reliability of the water level observations depend upon the soil type (water does not readily stabilize in a hole through fine grained soils), and that drill water used to advance the borings may have influenced the observations. The ground water level typically will fluctuate seasonally. One or more perched or trapped water levels may exist in the ground seasonally. All the available readings should be evaluated. If definite conclusions cannot be made, it is often prudent to examine the conditions more thoroughly through test pit excavations or water observation installations.
- ⑨ The length of core run is defined as length of penetration between retrievals of the core barrel from the bore hole, expressed in feet and tenths of feet. The core recovery expresses the length of core recovered from the core barrel per core run, i.e. percent. The size core barrel used is also noted. The more commonly used sizes of core barrels are denoted "AX" and "NX". The "NX" core, being larger in diameter than "AX" core, often produces better recovery, and is frequently utilized where accurate information regarding the geologic conditions and engineering properties is needed. The "NX" core barrel requires the use of four inch diameter casing.
